

Higher is better everywhere (↑). Difference is equilibrium – naive, so > 0 favours the equilibrium.

competitive reach σ/σ_0^*	commit to one expert (expected)			sequence-level mixture

Paired: identical test partition ($n = 5671$), identical pooled generalist (2.0152 nats), seed 0. Only the starting positions move.

Expected: equilibrium ahead at 8 of 10; mean +0.0007 but median +0.0027. The gap between them is reach 0.20, where the naive start is genuinely good: it beats its own split's mean in all four naive splits. Seed 0 exaggerates the size (excess +0.0220 against +0.0069, +0.0075, +0.0042), so the median is the better summary -- but the naive advantage there is real, not noise. Mixture: ahead at only 4 of 10, mean -0.0019. The equilibrium's edge is specific to committing to one expert; under mixing the two starts are level, and only the smoothness survives.

Roughness is mean lsecond differencel along the reach axis; it cancels trends, so it measures zigzag, not spread. The mixture columns both trend upward with reach, so SD is inflated equally for both and reports no difference; only the equilibrium's climb is near-monotone.

expected roughness naive 0.01643 vs equilibrium 0.00211 (7.8× smoother); steps rising with reach 3/8 vs 3/8

mixture roughness naive 0.01597 vs equilibrium 0.00358 (4.5× smoother); steps rising with reach 4/8 vs 7/8

Reach 0.70 is excluded from these footer statistics: its equilibrium is degenerate, placing seven pairs on five distinct positions.
